# Lecture 22

Exploration & Exploitation in  
Reinforcement Learning: MAB, UCB,  
Exp3

# How to balance exploration and exploitation in reinforcement learning

- Exploration:
  - try out each action/option to find the best one, gather more information for long term benefit
- Exploitation:
  - take the best action/option believed to give the best reward/payoff, get the maximum immediate reward given current information.
- Questions: Exploration-exploitation problems in real world?
  - Select a restaurant for dinner
  - ...

# Balancing exploration and exploitation

- Exploration:
  - try out each action/option to find the best one, gather more information for long term benefit
- Exploitation:
  - take the best action/option believed to give the best reward/payoff, get the maximum immediate reward given current information.
- **Questions: Exploration-exploitation problems in real world?**
  - Select a restaurant for dinner
  - Medical treatment in clinical trials
  - Online advertisement
  - Oil drilling
  - ...

# What's in the picture?

Picture is taken from Wikipedia

# Multi-armed bandit problem

- A gambler is facing at a row of slot machines. At each time step, he chooses one of the slot machines to play and receives a reward. The goal is to maximize his return.

A row of slot machines in Las Vegas

# Multi-armed bandit problem

- Stochastic bandits
  - Problem formulation
  - Algorithms
- Adversarial bandits
  - Problem formulation
  - Algorithms
- Contextual bandits

# Multi-armed bandit problem

- Stochastic bandits:
  - K possible arms/actions:  $1 \leq i \leq K$ ,
  - Rewards  $x_i(t)$  at each arm  $i$  are drawn iid, with an expectation/mean  $u_i$ , unknown to the agent/gambler
  - $x_i(t)$  is a bounded real-valued reward.
  - Goal : maximize the return(the accumulative reward.) or minimize the expected regret:
    - Regret =  $u^* T - \sum_{t=1}^T E[x_{i_t}(t)]$  , where
      - $u^* = \max_i[u_i]$ , expectation from the best action

# Multi-armed bandit problem: algorithms?

- Stochastic bandits:
  - Example: 10-armed bandits
  - Question: what is your strategy? Which arm to pull at each time step  $t$ ?

# Multi-armed bandit problem: algorithms

- Stochastic bandits: 10-armed bandits
- Question: what is your strategy? Which arm to pull at each time step  $t$ ?
- 1. Greedy method:
  - At time step  $t$ , estimate a value for each action
    - $Q_t(a) = \frac{\text{sum of rewards when } a \text{ taken prior to } t}{\text{number of times } a \text{ taken prior to } t}$
  - Select the action with the maximum value.
    - $A_t = \underset{a}{\operatorname{argmax}} Q_t(a)$
  - Weaknesses?

# Multi-armed bandit problem: algorithms

- 1. Greedy method:
  - At time step  $t$ , estimate a value for each action
    - $Q_t(a) = \frac{\text{sum of rewards when } a \text{ taken prior to } t}{\text{number of times } a \text{ taken prior to } t}$
  - Select the action with the maximum value.
    - $A_t = \underset{a}{\operatorname{argmax}} Q_t(a)$
- Weaknesses of the greedy method:
  - Always exploit current knowledge, no exploration.
  - Can stuck with a suboptimal action.

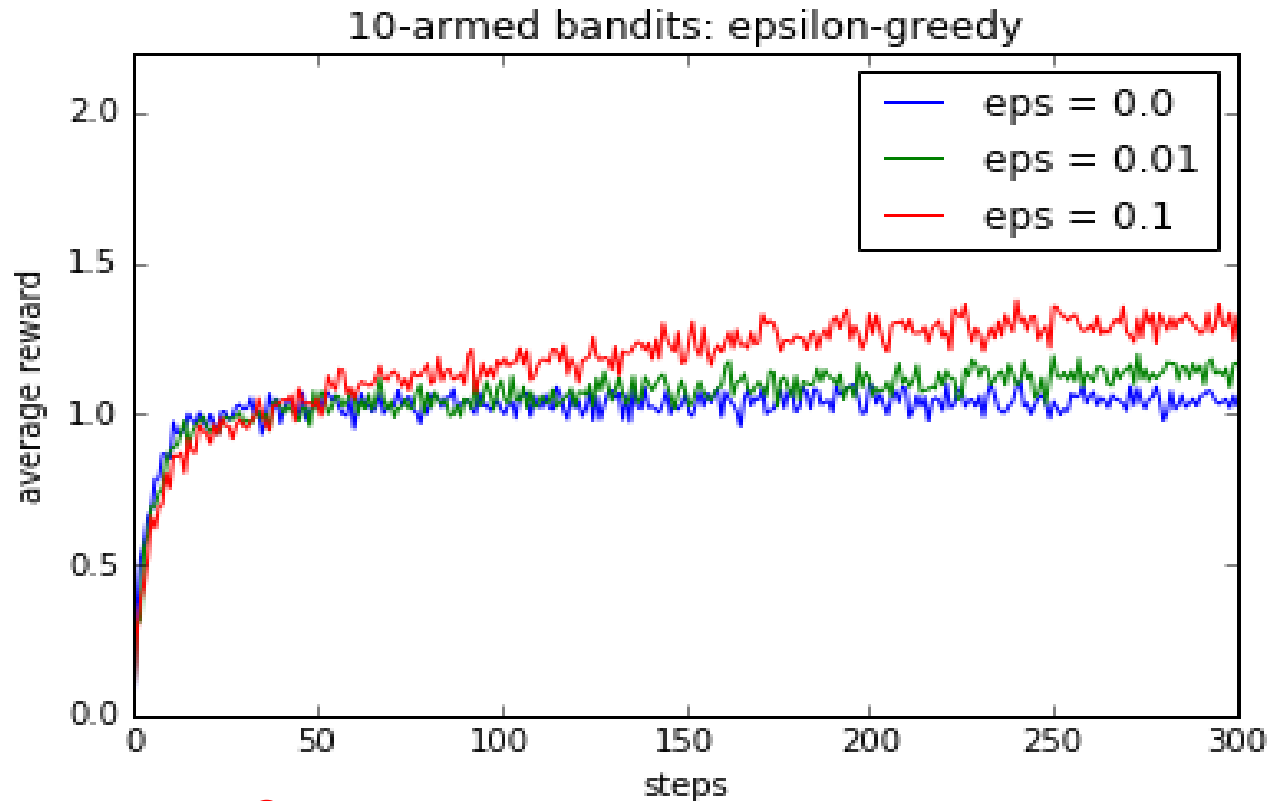

# Multi-armed bandit problem: algorithms

- 2.  $\epsilon$ -Greedy methods:
  - At time step  $t$ , estimate a value for each action
    - $Q_t(a) = \frac{\text{sum of rewards when } a \text{ taken prior to } t}{\text{number of times } a \text{ taken prior to } t}$
  - With probability  $1 - \epsilon$ , Select the action with the maximum value.
    - $A_t = \underset{a}{\operatorname{argmax}} Q_t(a)$
  - With probability  $\epsilon$ , select an action randomly from all the actions with equal probability.

# Experiments:

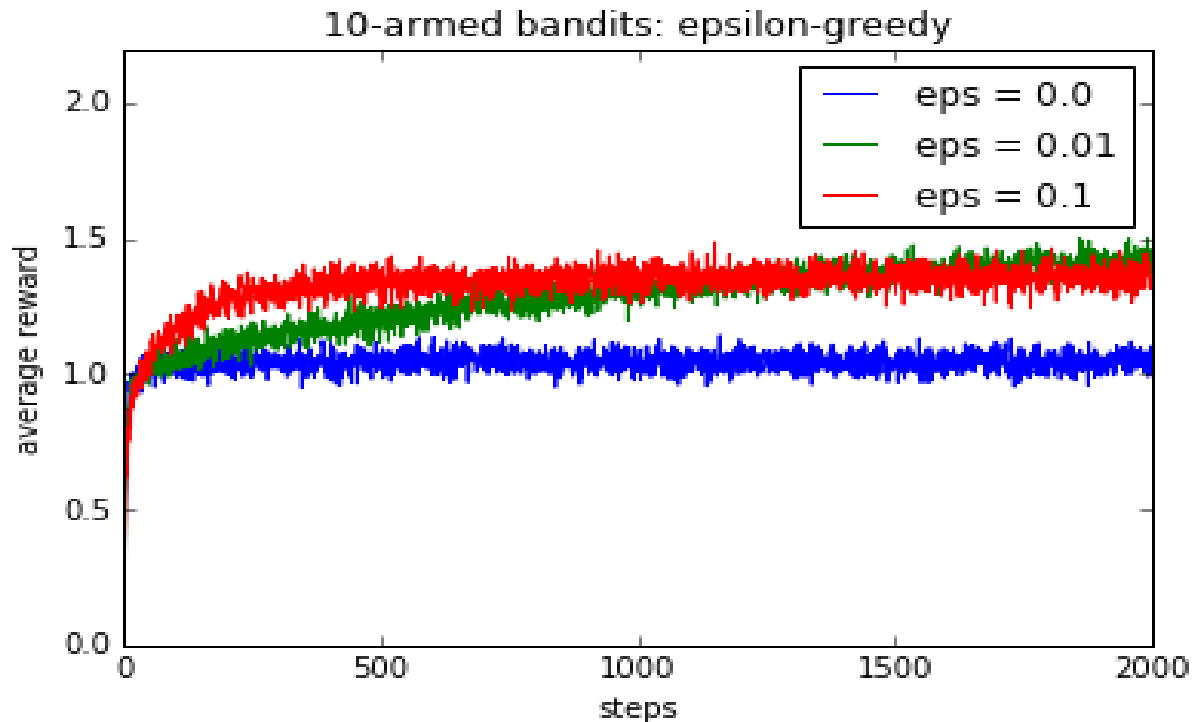

- Set up: (one run)
  - 10-armed bandits
  - Draw  $u_i$  from  $\text{Gaussian}(0,1)$ ,  $i = 1, \dots, 10$ 
    - the expectation/mean of rewards for action  $i$
  - Rewards of action  $i$  at time  $t$ :  $x_i(t)$ 
    - $x_i(t) \sim \text{Gaussian}(u_i, 1)$
  - Play 2000 rounds/steps
  - Average return at each time step
- Average over 1000 runs

# Experimental results: average over 1000 runs

Observations?

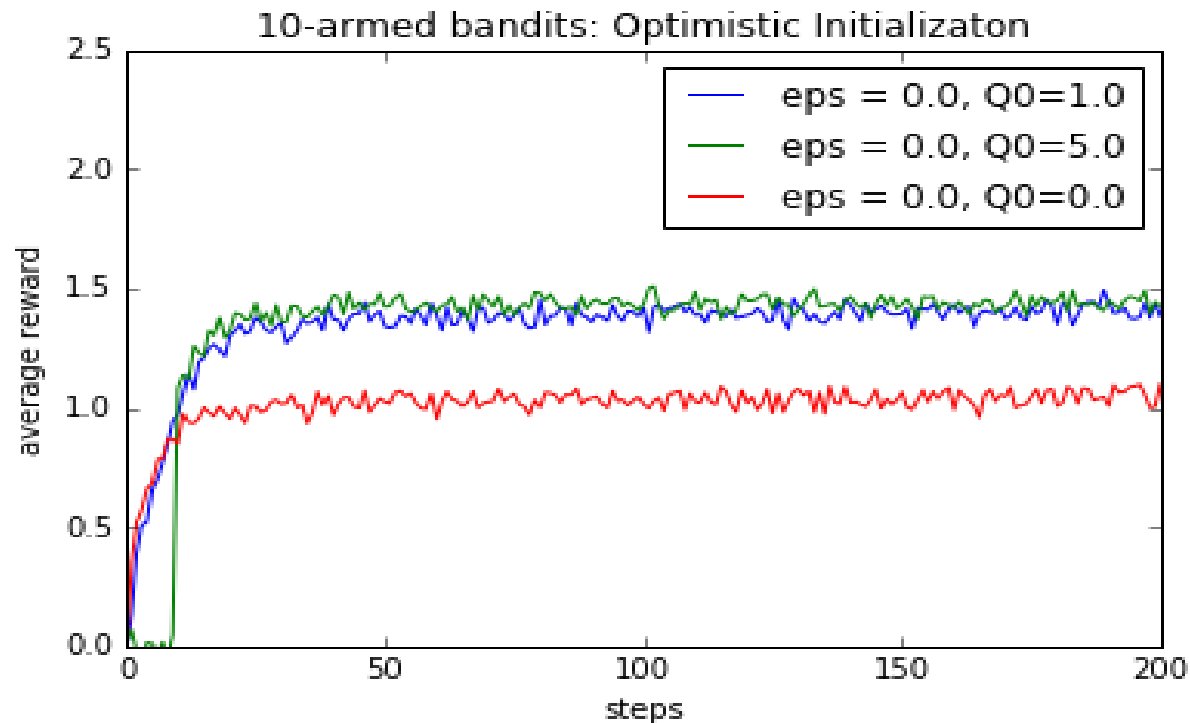

What will happen if we run more steps?

## Observations:

- Greedy method improved faster at the very beginning, but level off at a lower level.
- $\epsilon$ - Greedy methods continue to Explore and eventually perform better.
- The  $\epsilon = 0.01$  method improves slowly, but eventually performs better than the  $\epsilon = 0.1$  method.

# Improve the Greedy method with optimistic initialization

Observations:

# Greedy with optimistic initialization

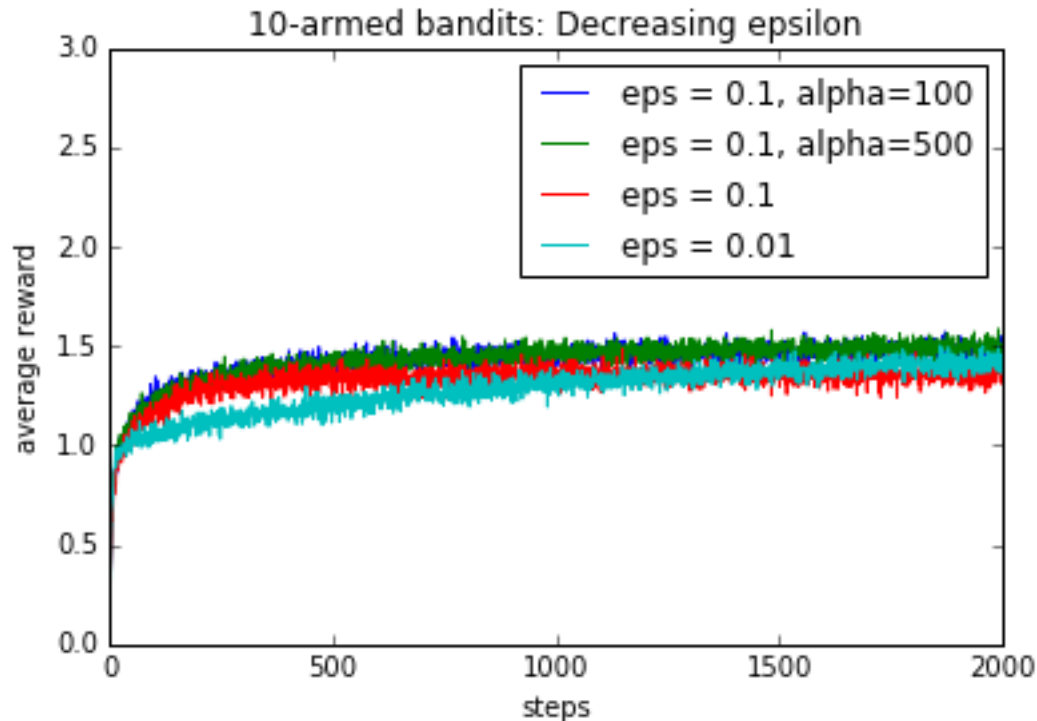

## Observations:

- Big initial Q values force the Greedy method to explore more in the beginning.
- No exploration afterwards.

# Improve $\epsilon$ -greedy with decreasing $\epsilon$ over time

## Decreasing over time:

- $\epsilon_t = \epsilon_t * (\alpha)/(t + \alpha)$
- Improves faster in the beginning, also outperforms fixed  $\epsilon$ -greedy methods in the long run.

# Weaknesses of $\epsilon$ -Greedy methods:

- $\epsilon$ -Greedy methods:
  - At time step  $t$ , estimate a value  $Q_t(a)$  for each action
  - With probability  $1 - \epsilon$ , Select the action with the maximum value.
    - $A_t = \underset{a}{\operatorname{argmax}} Q_t(a)$
  - With probability  $\epsilon$ , select an action randomly from all the actions with equal probability.
- Weaknesses:

# Weaknesses of $\varepsilon$ -Greedy methods:

- $\varepsilon$ -Greedy methods:
  - At time step  $t$ , estimate a value  $Q_t(a)$  for each action
  - With probability  $1 - \varepsilon$ , Select the action with the maximum value.
    - $A_t = \underset{a}{\operatorname{argmax}} Q_t(a)$
  - With probability  $\varepsilon$ , select an action randomly from all the actions with equal probability.
- **Weaknesses:**
  - Randomly selects a action to explore, does not explore more “promising” actions.
  - Does not consider confidence interval. If an action has been taken many times, no need to explore it.

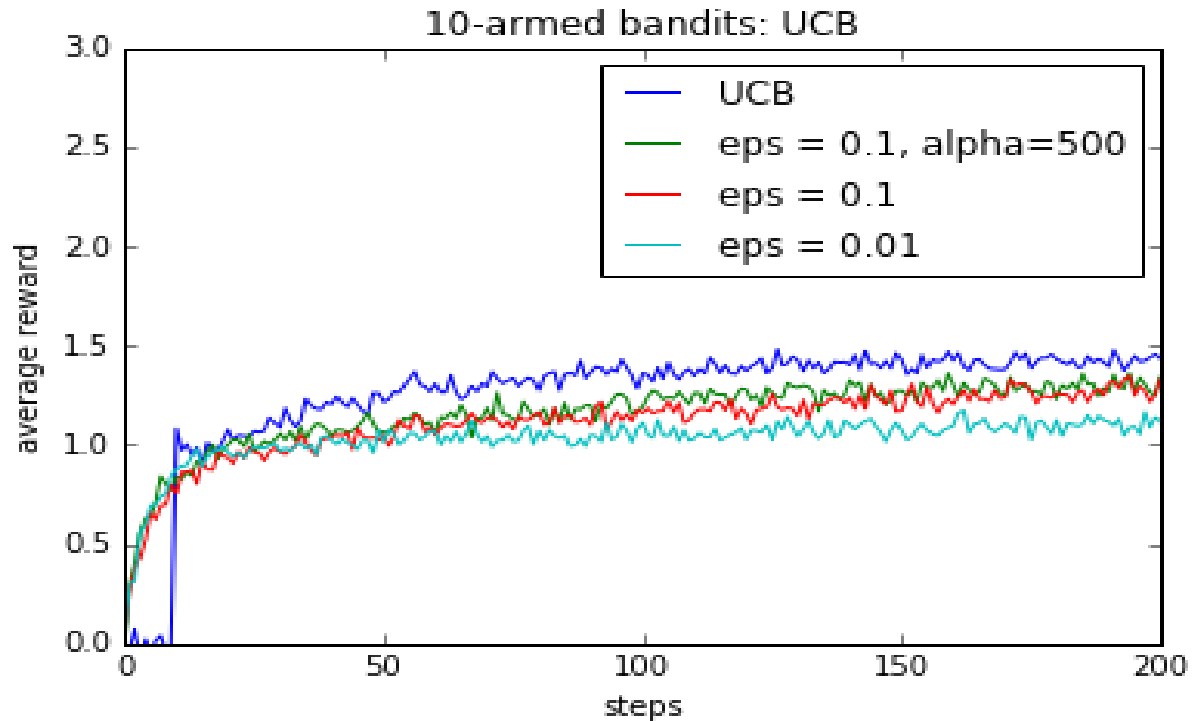

# Upper Confidence Bound algorithm

- Take each action once.
- At any time  $t > K$ ,
  - $A_t = \operatorname{argmax}_a (Q_t(a) + \sqrt{\frac{2 \ln t}{N_a(t)}})$ , where
    - $Q_t(a)$  is the average reward obtained from action  $a$ ,
    - $N_a(t)$  is the number of times action  $a$  has been taken.

# Upper Confidence Bounds

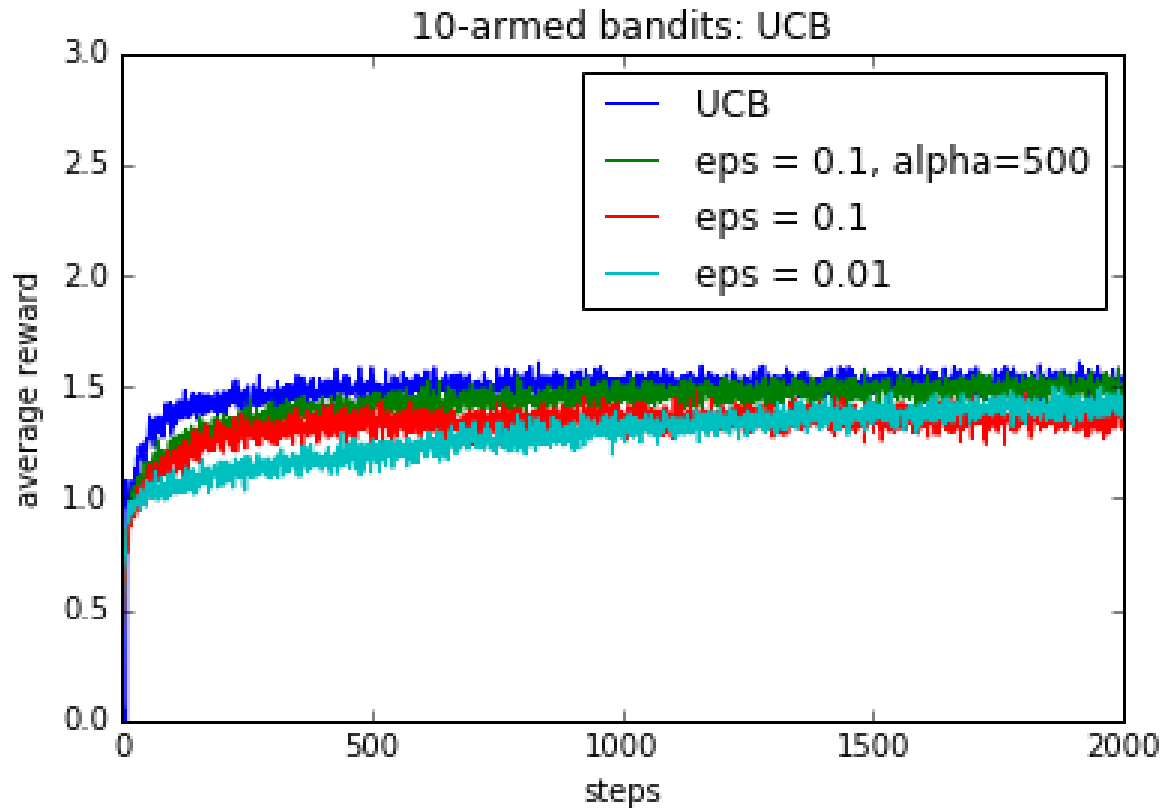

- $A_t = \operatorname{argmax}_a (Q_t(a) + \sqrt{\frac{2 \ln t}{N_a(t)}})$
- $\sqrt{\frac{2 \ln t}{N_a(t)}}$  is confidence interval for the average reward,
- Small  $N_a(t) \rightarrow$  large confidence interval ( $Q_t(a)$  is more uncertain)
- large  $N_a(t) \rightarrow$  small confidence interval ( $Q_t(a)$  is more accurate)
- select action maximizing upper confidence bound.
  - Explore actions which are more uncertain, exploit actions with high average rewards obtained.
  - UCB: balance exploration and exploitation.
  - As  $t \rightarrow$  infinity, select optimal action.

# How good is UCB? Experimental results

Observations:

# How good is UCB? Experimental results

**Observations:** After initial 10 steps, improves quickly and outperforms  $\epsilon$ -Greedy methods.

# How good is UCB? Theoretical guarantees

- Expected regret is bounded by

$$8^* \sum_{u_i < u^*} \frac{\ln t}{u^* - u_i} + \left(1 + \frac{\pi^2}{3}\right) \sum_{i=1}^K (u^* - u_i)$$

- Achieves the optimal regret up to a multiplicative constant.
- Expected regret grows in  $O(\ln t)$

# How is the UCB derived?

- Hoeffding's Inequality Theorem:
- Let be  $X_1, \dots, X_t$  i.i.d. random variables in  $[0,1]$ , and let  $\bar{X}_t$  be the sample mean, then
  - $P[E[\bar{X}_t] \geq \bar{X}_t + u] \leq e^{-2tu^2}$
- Apply to the bandit rewards,
  - $P[Q(a) \geq Q_t(a) + V_t(a)] \leq e^{-2N_t(a)V_t(a)^2}$ ,
  - $2 * V_t(a)$  is size of the confidence interval for  $Q(a)$
  - $p = e^{-2N_t(a)V_t(a)^2}$  is the probability of making an error

# How is the UCB derived?

- Apply to the bandit rewards,
  - $P[Q(a) > Q_t(a) + V_t(a)] \leq e^{-2N_t(a)V_t(a)^2}$
- Let  $p = e^{-2N_t(a)V_t(a)^2} = t^{-4}$ ,
- Then  $V_t(a) = \sqrt{\frac{2 \ln t}{N_a(t)}}$
- Variations of UCB1 (the basic one here):
  - UCB1\_tuned, UCB3, UCBv, etc.
  - Provide and prove different upper bounds for the expected regret.
  - Add a parameter to control the confidence level

# Multi-armed bandit problem

- Stochastic bandits
  - Problem formulation
  - Algorithms:
    - Greedy,  $\epsilon$ -greedy methods, UCB
    - Boltzmann exploration(Softmax)
- Adversarial bandits
  - Problem formulation
  - Algorithms
- Contextual bandits

# Multi-armed bandit problem

- Boltzmann exploration(Softmax)
  - Pick a action with a probability that is proportional to its average reward.
  - Actions with greater average rewards are picked with higher probability.
- The algorithm:
  - Given initial empirical means  $u_1(0), \dots, u_K(0)$
  - $$p_i(t+1) = \frac{e^{u_i(t)/\tau}}{\sum_{j=1}^K e^{u_j(t)/\tau}}, \quad i = 1, \dots, K$$
  - *What is the use of  $\tau$  ?*
  - *What happens as  $\tau \rightarrow \text{infinity}$ ?*

# Multi-armed bandit problem

- Boltzmann exploration(Softmax)
  - Pick a action with a probability that is proportional to its average reward.
  - Actions with greater average rewards are picked with higher probability.
- The algorithm:
  - Given initial empirical means  $u_1(0), \dots, u_K(0)$
  - $p_i(t+1) = \frac{e^{u_i(t)/\tau}}{\sum_{j=1}^K e^{u_j(t)/\tau}}$ ,  $i = 1, \dots, K$
  - $\tau$  controls the choice.
  - *as  $\tau \rightarrow$  infinity, selects uniformly.*

# Multi-armed bandit problem

- Stochastic bandits
  - Problem formulation
  - Algorithms:
    - $\epsilon$ -greedy methods, UCB
    - Boltzmann exploration(Softmax)
- Adversarial bandits
  - Problem formulation
  - Algorithms
- Contextual bandits

# Non-stochastic/adversarial multi-armed bandit problem

- Setting:
  - $K$  possible arms/actions:  $1 \leq i \leq K$ ,
  - each action is denoted by an assignment of rewards.  $x(1), x(2), \dots$ , of vectors  $x(t) = (x_1(t), x_2(t), \dots, x_K(t))$
  - $x_i(t) \in [0, 1]$  : reward received if action  $i$  is chosen at time step  $t$  (can generalize to in the range  $[a, b]$ )
  - Goal : maximize the return (the accumulative reward.)
- Example.  $K=3$ , an adversary controls the reward.

k	t=1	t=2	t=3	t=4	...
1	0.2	0.7	0.4	0.3	
2	0.5	0.1	0.6	0.2	
3	0.8	0.4	0.5	0.9	

# Adversarial multi-armed bandit problem

- Weak regret =  $G_{\max}(T) - G_A(T)$
- $G_{\max}(T) = \max_j \sum_{t=1}^T x_j(t)$ , return of the single global best action at time horizon T
- $G_A(T) = \sum_{t=1}^T x_{i_t}(t)$ , return at time horizon T of algorithm A choosing actions  $i_1, i_2, \dots$
- Example.  $G_{\max}(4) = ?$ ,  $G_A(4) = ?$ 
  - (\* indicates the reward received by algorithm A at a time step t)

K/T	t=1	t=2	t=3	t=4	...
1	0.2	0.7	0.4	0.3*	
2	0.5*	0.1	0.6*	0.2	
3	0.8	0.4*	0.5	0.9	

# Adversarial multi-armed bandit problem

- Example.  $G_{\max}(4)=?$ ,  $G_A(4)=?$ 
  - $G_{\max}(4) = \max_j \sum_{t=1}^T x_j(t) = \max\{G_1(4), G_2(4), G_3(4)\}$   
 $= \max\{1.6, 1.4, 2.4\} = 2.4$
  - $G_A(4) = \sum_{t=1}^T x_{i_t}(t) = 0.5 + 0.4 + 0.6 + 0.3 = 1.8$
- Evaluate a randomized algorithm A: Bound on the expected regret for a A:  $G_{\max}(T) - E[G_A(T)]$

K/T	t=1	t=2	t=3	t=4	...
1	0.2	0.7	0.4	0.3*	
2	0.5*	0.1	0.6*	0.2	
3	0.8	0.4*	0.5	0.9	

# Exp3: exponential-weight algorithm for exploration and exploitation

- Parameter:  $\gamma \in (0,1]$
- Initialize:
  - $w_i(1) = 1$  for  $i = 1, \dots, K$
- for  $t=1, 2, \dots$ 
  - Set  $p_i(t) = (1-\gamma) \frac{w_i(t)}{\sum_{j=1}^K w_j(t)} + \gamma \cdot \frac{1}{K}$ ,  $i = 1, \dots, K$
  - Draw  $i_t$  randomly from  $p_1(t), \dots, p_K(t)$
  - Receive reward  $x_{i_t} \in [0,1]$
  - For  $j = 1, \dots, K$ 
    - $\widehat{x_j(t)} = x_j(t) / p_j(t)$  if  $j=i_t$
    - $\widehat{x_j(t)} = 0$  otherwise
    - $w_j(t+1) = w_j(t) \cdot \exp(\gamma \cdot \widehat{x_j(t)} / K)$

Question: what happens at time step 1? At time step 2?  
What happens as  $\gamma \rightarrow 1$ ? Why  $x_j(t) / p_j(t)$ ?

# Exp3: Balancing exploration and exploitation

- $p_i(t) = (1 - \gamma) \frac{w_i(t)}{\sum_{j=1}^K w_j(t)} + \gamma \cdot \frac{1}{K}$  ,  $i = 1, \dots, K$
- Balancing exploration and exploitation in Exp3
  - The distribution  $P(t)$  is a mixture of the uniform distribution and a distribution which assigns to each action a probability mass exponential in the estimated cumulative reward for that action.
  - Uniform distribution encourages exploration
  - The other probability encourages exploitation
  - The parameter  $\gamma$  controls the exploration.
  - $x_j(t) / p_j(t)$  compensate the reward of actions that are unlikely to be chosen

# Exp3: How good is it?

- Theorem:

For any  $K > 0$  and for any  $\gamma \in (0, 1]$ ,

$$G_{\max} - E[G_{\text{Exp3}}] \leq (e-1) * \gamma * G_{\max} + K * \ln(K) / \gamma$$

Holds for any assignment of rewards and for any  $T > 0$

- Corollary:

- For any  $T > 0$ , assume that  $g \geq G_{\max}$  and that algorithm Exp3 is run with the parameter

- $\gamma = \min \left\{ 1, \sqrt{\frac{K \ln K}{(e-1)g}} \right\},$

- Then  $G_{\max} - E[G_{\text{Exp3}}] \leq 2\sqrt{(e-1)} \sqrt{gK \ln k} \leq 2.63\sqrt{gK \ln k}$

# A family of Exp3 algorithms

- Exp3, Exp3.1, Exp3.P, Exp4, ...
- Better performance
  - tighter upper bound,
  - achieve small weak regret with high probability, etc.
- Changes based on Exp3
  - How to choose  $\gamma$
  - How to initialize and update the weights  $w$

# Summary: Exploration & exploitation in Reinforcement learning

- Stochastic bandits
  - Problem formulation
  - Algorithms
    - $\epsilon$ - greedy methods, UCB, Boltzmann exploration(Softmax)
- Adversarial bandits
  - Problem formulation  $u^* - u$
  - Algorithms: Exp3
- Contextual bandits
  - At each time step  $t$ , observes a feature/context vector.
  - Uses both context vector and rewards in the past to make a decision
  - Learns how context vector and rewards relate to each other.
